Antimalarials improve survival of systemic lupus erythematosus on cholesterol: Results of a fifteen-year Chinese multicenter retrospective study in Jiangsu province

Background and aims Nowadays the importance of antimalarials, especially hydroxychloroquine (HCQ) and chloroquine (CQ), in treatment of systemic lupus erythematosus (SLE) has been demonstrated. However, few have examined the efficacy of HCQ and CQ on eastern Chinese SLE patients.

Methods The analysis is based on 1372 patients who were enrolled in a retrospective study of 26 centres from January 1st, 1999 through December 31st, 2009, during which time is their first hospitalisation. Baseline and follow-up clinical, laboratory and therapeutic data and survival status before April 30th, 2015 were recorded. Statistical analysis consist of Chi-square test, t-test, Kaplan-Meier curves and logrank test.

Results Compared with 562 patients without HCQ or CQ treatment, the hazard ratio (HR) of deaths in 810 patients taking those was reduced (HR 0.52, 95% CI 0.38–0.70, p<0.001). 376 of these 1372 patients experienced their second hospitalisation, during which treating group (165 of 376) showed high blood level of total cholesterol (TG), compared to control group (4.47 (0.13) vs 5.03 (0.21), p=0.027), while no statistical difference of TG exists between the two groups (p>0.05). Other metabolic data, such as systolic and diastolic blood pressure, fasting blood sugar, triglyceride and uric acid were similar between the two groups in two times of hospitalisation. On second inpatient visit, disease activity (SLE disease activity index, blood sedimentation rate, complement) and organ involvements of antimalarials takers and no users showed no significant differences either.

Conclusions Use of HCQ or CQ lower the risk of mortality and TG levels of eastern Chinese SLE patients.

Standardised mortality ratio, outcome and prognostic factors of neuropsychiatric systemic lupus erythematosus: A real world single centre study

Background and aims To investigate the survival rate and prognostic factors of neuropsychiatric systemic lupus erythematosus (NPSLE) in a cohort.

Methods A total of 101 NPSLE inpatients diagnosed in a single centre from 2005 to 2016 were included. Information on survival status, date and causes of death was acquired by follow-up. Data were analysed using Kaplan-Meier curves, log-rank tests and Cox proportional hazards modelling.

Results The overall survival rates of the NPSLE cohort were 89%, 85% and 84% at 1, 3 and 5 years respectively. The standardised mortality ratio (SMR) of NPSLE patients was 11.14. The most common cause of death was NPSLE (7, 47%), including intracranial hypertension syndrome (4, 27%), cerebrovascular disease (2, 13%) and motor neuron disease (1, 7%). The remaining causes included other SLE complications (3, 20%) and infection (2, 13%). Crude analysis showed that the following variables at diagnosis were associated with a shorter survival period: cardiac involvement, renal involvement, diffuse NPSLE, acute confusional state, number of NPSLE manifestations >1, lymphocyte <10^9/L, elevated C-reactive protein (CRP), abnormal cerebrospinal fluid and high systemic lupus erythematosus disease activity index (SLEDAI). On multivariate analysis, acute confusional state (p=0.004), high SLEDAI (p=0.020) and elevated CRP (p=0.023) were independently prognostic of death.

Conclusions Our study demonstrate an 11.14-fold increased mortality of NPSLE patients compared with general population. NPSLE itself is the most frequent cause of death. Acute confusional state is the most significant predictive factor for poor prognosis.
The definition of LLDAS was applied: (1) SLEDAI-2K £ 4, with no activity in major organ systems (renal, central nervous system, cardiopulmonary, vasculitis, fever) and no haemolytic anaemia or gastrointestinal activity; (2) no new lupus activity compared with the previous assessment; (3) a PGA (scale 0–3) £ 1; (4) current prednisolone-equivalent dose £ 7.5 mg/day; (5) stable maintenance dose of immunosuppressants.

The effect of different durations of LLDAS (1, 2, 3, 4, 5 consecutive years) on SDI was evaluated by multivariate logistic regression analysis.

**Results**

The prevalence of LLDAS and damage in the cohort are reported in Table 1.

Patients who spent at least 2 consecutive years in LLDAS had significantly reduced damage accrual compared with patients never in LLDAS (p=0.001). Interestingly, among the 254 patients achieving LLDAS for at least 1 year, 231 (90.9%) had clinical-SLEDAI-2K=0. At multivariate analysis, a LLDAS lasting at least two years was protective against damage (Table 2). Conversely, major independent predictors of damage were cumulative prednisone dose £ 180 mg/month and antiphospholipid antibody syndrome (Table 2).

**Conclusions**

Two consecutive years was the shortest LLDAS duration associated with a decrease in damage progression in Caucasian SLE patients.

**465 SULFASALAZINE-RELATED HYPERSENSITIVITY REACTIONS IN PATIENTS WITH RHEUMATIC DISEASES**

T Sentürk*, S Cildag, Adnan Menderes University – Medical Faculty, Rheumatology, Aydin, Turkey

**Background and aims**

Sulfonamide related allergic drug reactions are common, and their rate is reported to be 3.0% for the general population. Sulfasalazine (SSZ), which is an inflammatory drug in the arylamine sulfonamide structure, is being used for the treatment of many rheumatic diseases. In this study, we aimed to determine the frequency of sulfasalazine-related hypersensitivity reactions in patients with rheumatic disease.

**Methods**

A total of 136 patients (84 RA and 52 AS) were included in this study. Patients were screened for those who recently started using sulfasalazine treatment. The type of the reaction, duration of the reaction, administered medicines, and their doses were recorded in patients with detected hypersensitivity during the follow-up. The drug was stopped and antihistaminic and/or corticosteroid treatment was administered as needed. In patients with a negative prick test, a drug provocation test (DPT) was performed after drugs were stopped and amino salicylic acid.

**Results**

A total of 136 patients, with ages ranging from 19 to 71 (mean 41.97±12.04), were included in the study.
